Randomized Efficacy Trial of Two Psychotherapies for Depression in Youth With Inflammatory Bowel Disease

Eva Szigethy, MD, PhD, Simona I. Bujoreanu, PhD, Ada O. Youk, PhD, John Weisz, PhD, David Benhayon, MD, PhD, Diane Fairclough, DrPh, Peter Ducharme, LICSW, Joseph Gonzalez-Heydrich, MD, David Keljo, MD, Arvind Srinath, MD, Athos Bousvaros, MD, Margaret Kirshner, BA, Melissa Newara, MS, David Kupfer, MD, David R. DeMaso, MD

Objective: Pediatric inflammatory bowel disease (IBD) is associated with high rates of depression. This study compared the efficacy of cognitive behavioral therapy (CBT) to supportive nondirective therapy (SNDT) in treating youth with comorbid IBD and depression. Method: Youth (51% female and 49% male; age 9–17 years, mean age 14.3 years) with depression and Crohn’s disease (n = 161) or ulcerative colitis (n = 56) were randomly assigned to a 3-month course of CBT or SNDT. The primary outcome was comparative reduction in depressive symptom severity; secondary outcomes were depression remission, increase in depression response, and improved health-related adjustment and IBD activity. Results: A total of 178 participants (82%) completed the 3-month intervention. Both psychotherapies resulted in significant reductions in total Children’s Depression Rating Scale Revised score (37.3% for CBT and 31.9% for SNDT), but the difference between the 2 treatments was not significant (p = .16). There were large pre–post effect sizes for each treatment (d = 1.31 for CBT and d = 1.30 for SNDT). More than 65% of youth had a complete remission of depression at 3 months, with no difference between CBT and SNDT (67.8% and 63.2%, respectively). Compared to SNDT, CBT was associated with a greater reduction in IBD activity (p = .04) but no greater improvement on the Clinical Global Assessment Scale (p = .06) and health-related quality of life (IMPACT-III scale) (p = .07). Conclusion: This is the first randomized controlled study to suggest improvements in depression severity, global functioning, quality of life, and disease activity in a physically ill pediatric cohort treated with psychotherapy. Clinical trial registration information—Reducing Depressive Symptoms in Physically Ill Youth; http://clinicaltrials.gov; NCT00534911. J. Am. Acad. Child Adolesc. Psychiatry, 2014;53(7):726–735. Key Words: depression, quality of life, physical illness, psychotherapy, inflammatory bowel disease

Youth with chronic physical illnesses experience a disproportionate burden of depression associated with worse medical outcomes and poor health-related quality of life (HRQoL). With a US prevalence of 71 in 100,000, inflammatory bowel disease (IBD) is a lifelong illness involving episodic inflammation of the gastrointestinal tract. The treatment of IBD, which includes Crohn’s disease (CD) and ulcerative colitis (UC), often requires immunosuppressive medication and/or surgical resection for severe disease.

Compared to healthy youth and those with other physical illnesses, youth with IBD have elevated rates (10%–25%) of depression and poorer quality of life. Findings suggest that depression in pediatric IBD is a heterogeneous condition with etiologically different subtypes (mild–low-grade symptoms, somatic–IBD-related symptoms, and cognitive–cognitive despair symptoms), making psychiatric treatment challenging.

Although psychotherapies for depression are relatively effective for improving mood and
HRQoL in adults with IBD, such treatments are understudied in youth with IBD. Studies have shown that cognitive behavioral therapy (CBT) reduced depressive symptoms and improved functioning in pediatric IBD compared to standard medical treatment. The CBT used in these studies was Primary and Secondary Control Enhancement Training for Physical Illness (PASCET-PI), which is based on the concept that perceived control and attention to physical illness narrative can mediate the relationship between disease and psychological outcomes. Attention to illness narrative in PASCET-PI was based on adult IBD studies showing that pessimistic illness perceptions were related to poorer psychological adjustment.

This study compared CBT to supportive non-directive therapy (SNdT) in treating depression (primary outcome) and enhancing HRQoL and reducing disease activity (secondary outcomes) in comorbid pediatric IBD and depression after 3 months of treatment. This study explored the change in depression over time in treatment groups. Shown to reduce negative affectivity in other physical illnesses, SNdT was chosen to control for the nonspecific aspects of psychotherapy (i.e., time and contact with an empathic and skilled therapist). Although both interventions were hypothesized to reduce depression, to improve HRQoL, and to diminish IBD activity, it was expected that these effects would be greater in youth receiving PASCET-PI.

**METHOD**

**Participants**

Participants with IBD as determined by gastroenterologists using the Porto Criteria, aged 9–17 years, were recruited from Children’s Hospital of Pittsburgh and Boston Children’s Hospital. Each site was approved by its institutional review board. Parents provided informed consent, and youth provided assent.

Participants were screened for depression with the Children’s Depression Inventory (CDI). CDI scores ≥10 on either child or parent rating were considered to be associated with clinically significant depressive symptoms and led to assessment with the Kiddie-Schedule for Affective Disorders and Schizophrenia–Present Version (K-SADS-PL). The K-SADS-PL is a validated, semi-structured diagnostic interview of youth and parents that assesses the presence of DSM-IV-TR psychiatric disorders. Based on randomly selecting 20% of the youth, interrater reliability for depression diagnosis was 0.60 at pretreatment and 0.70 at 3 months.

**Assessment Instruments for Depression**

Children’s Depression Inventory (CDI). The CDI is a 27-item self-report measure that assesses depression symptom severity. This well-validated psychometric measure has child and parent versions (CDI-Child and CDI-Parent), and has been used to reliably diagnose depression in those with physical illnesses, including IBD.

Kiddie-Schedule for Affective Disorders and Schizophrenia–Present Version (K-SADS-PL). The K-SADS-PL is a validated, semi-structured diagnostic interview of youth and parents that assesses the presence of DSM-IV-TR psychiatric disorders. Based on randomly selecting 20% of the youth, interrater reliability for depression diagnosis was 0.60 at pretreatment and 0.70 at 3 months.

**Assessment Instruments for Health-related Adjustment**

IMPACT-III Questionnaire. The IMPACT-III Questionnaire is a validated, 35-item, self-report HRQoL measure for pediatric IBD. It has the following domains: bowel symptoms, extraintestinal symptoms, emotional functioning, social functioning, body image, and treatment/interventions. The maximal score is 175, with higher scores associated with better HRQoL.
Children’s Global Assessment Scale (CGAS). The CGAS is a clinician-rated numeric scale used to assess psychosocial functioning. It is stratified by degrees of impairment. A blinded assessor rated degree of functional impairment due to depression and/or IBD activity.

Assessment Instruments for Disease Activity

Pediatric Crohn’s Disease Activity Index (PCDAI). The PCDAI is a well-validated scale used to determine CD activity by measuring the following domains: self-report of pain and stool consistency; functional disability; and objective physical/laboratory data (e.g., erythrocyte sedimentation rate [ESR], hematocrit, albumin, growth, and physical examination).

Pediatric Ulcerative Colitis Activity Index (PUCAI). The PUCAI is a validated symptom-based score used for UC activity and is based on self-ratings of abdominal pain, rectal bleeding, stool consistency, stool frequency, presence/absence of nocturnal stooling, and activity level.

PCDAI >30 and PUCAI >35 are consistent with at least moderate disease activity and correlate with gastrointestinal inflammation. Both measures were rated by a blinded gastroenterologist. Because the PCDAI and PUCAI yield different indices, both measures were separately converted to z scores to combine them into 1 disease activity variable.

Medical History. Medical history (including IBD onset, presentation, course, and disease location using the Paris classification schema, medication use [e.g., steroids, biologics, and/or immunomodulators], surgical history, and ostomy status) was obtained from parents and medical records. Systemic inflammatory biomarkers (C-reactive protein and ESR) were obtained from the medical record by a blinded gastroenterologist. IBD course was divided into acute (diagnosis ≤6 months), chronic (diagnosis >6 months with <1 month in remission defined by inactive PCDAI/PUCAI score), and chronic intermittent (diagnosis >6 months with at least 1 month of remission).

Demographic Information. Demographic information was obtained using an information sheet (age, race, gender, household income) and an occupation-based measure. Socioeconomic status was defined as household income divided by the number of household individuals.

Interventions

Interventions (up to twelve 45-minute sessions over 3 months) were provided by therapists (n = 10) experienced in treating physically ill youth (master’s-level counselors, social workers, psychology interns, psychologists, child psychiatry fellows, and psychiatrists). Each therapist underwent a 3-day training program with the PASCET-PI and SNDT therapy manuals with didactic and practice components as well as viewing an 8-hour PASCET-PI training video. Each therapist received weekly supervision with at least master’s-level therapists expert in the interventions. Each session was audiotaped. The therapist filled out a key skill checklist form for each PASCET-PI session. If key CBT skills were lacking in supervision, therapists were directed to cover missed content during the flexible therapy sessions (9–12).

Although key intervention skills remained the same, treatment was tailored to a youth’s individual developmental level. For participants aged 9 to 13 years receiving CBT, handouts and practice assignments were simplified; pictures were used to illustrate concepts; skills became part of games; and parents were involved after each individual session to review practice assignments. In SNDT, conversations with participants aged 9 to 13 years were conducted during games, and parents were involved after each session to review their child’s progress. Given the wide geographic areas for participants at each site, >62% of the CBT and >70% of the SNDT sessions were completed by telephone, with results similar to those in other studies evaluating phone therapy for depression. Three parent sessions were provided in each therapy; for CBT this was to reinforce skills, and for SNDT it was to listen empathically to parent concerns (Table 1).

Participants were randomly assigned to CBT or SNDT and balanced with regard to age (9–13 versus 14–17), IBD type (CD versus UC), and depressive severity (minor versus major) using a block design randomization schema. Randomization was completed separately at each site to achieve balance across covariates within each site. The randomization scheme was designed using an adaptive procedure in which the probability of assignment depended on the balance of previous assignments within a strata, so that no more than 2 participants could be successively assigned to 1 treatment.

Illness Narrative Probe. In session 1 of both interventions, therapists conducted an open-ended, semi-structured interview consisting of 10 questions exploring illness representation and experience. The questions covered domains identified in theoretical illness perception models: identity—the personal label and symptoms as part of participants’ illness; cause—personal ideas about the etiology of their illness; timeline—beliefs on how long their illness will last; consequences—patient-anticipated effects of their illness; and cure/control—perceived recovery form or control over their illness. These domains were used as topics in SNDT and as potential problems to target in CBT.

CBT. PASCET-PI focused on teaching new ways of behaving and thinking by recognizing and challenging automatic negative thoughts, particularly related to IBD symptoms (Table 1). Weekly practice assignments were focused on behavioral activation and cognitive reframing. Three parent sessions focused on parent coaching and encouraging their children to use the CBT skills.

SNDT. Sessions focused on establishing/maintaining rapport, providing social/emotional support via
reflective listening, providing empathy, and encouraging youth to seek out resources for help. In contrast to CBT, therapists refrained from teaching specific skills, and there were no intersession practice assignments. The 3 parent sessions consisted of listening to parental concerns.

**Intervention Fidelity.** A total of 21% of participants (n = 23 per group) were randomly selected and rated by a separate assessor using adherence checklists.

**Statistical Analyses**

Descriptive statistics were computed for demographic and clinical measures for the entire cohort and each treatment group. t Tests and χ² tests were used where appropriate to assess differences in these variables between treatment groups; χ² tests were used to assess differences between treatments in treatment responders (≤28 on CDRS-R posttreatment, secondary) and depression remission (defined as no longer meeting KSADS-PL criteria for a depressive diagnosis posttreatment, secondary).

Main analyses were performed using linear mixed models that allowed missing data under the assumption of missing at random. In addition, a completer analysis was performed restricting the analyses to those who completed both time points (n = 178), and the results remained similar. No data imputations were performed, and all available data points were used.

Linear mixed-effects models assessed the treatment impact (CBT versus SNDT) on CDRS-R (primary outcome), CGAS, IMPACT-III, and pooled IBD activity (secondary outcomes) over time (baseline to 3 months) in intent-to-treat analyses controlling for site. Change from baseline of these continuous scores was modeled as a function of time and the interaction of treatment and time. Because participants were randomized into each treatment group, baseline scores for each treatment were set to be equal in the model by not including the main effect of

treatment. For outcomes with statistically significant baseline group differences, we fit an additional model allowing baseline scores to be different by including the main effect of treatment. Effect sizes for the treatment impact were computed for CDSS-R scores using a pre–post design based on Cohen’s d estimate.

Statistical significance was determined using Wald tests (t tests) from the linear mixed models using $\alpha = 0.05$ (2-sided). All analyses were performed using Stata version 12.41 For secondary depressive outcomes (responder and remission), Bonferroni correction for multiple comparisons was used because the outcomes are related. For the secondary outcomes of health-related adjustment and disease activity, no such correction was made, as these outcomes probe different domains, and as this is a unique study of a comorbid psychiatric–medical cohort, we wanted to retain its heuristic, hypothesis-generating potential by reporting all findings.

RESULTS
Sample and Intervention Characteristics
A total of 765 youths were screened with 217 meeting randomization criteria; 161 with CD and 56 with UC (Figure 1 and Table 2). At baseline, 1 potential participant was excluded for severe depression, and 6 participants were excluded for being on antidepressants. The treatment groups were significantly different only for white race (CBT 94.6%, SNDT 84.1%), surgical resection rate (CBT 5.6%, SNDT 14.2%), and raw mean baseline CDSS-R scores (CBT 45.1, SNDT 48.9). There were no significant differences in levels of medical adherence at baseline (total 88%: CBT 92%, SNDT 85%).

DSM-IV-TR psychiatric comorbidities included the following: generalized anxiety disorder (GAD; 21.7%), specific phobia (15.2%), attention-deficit/hyperactivity disorder (ADHD; 11.6%), separation anxiety (SAD; 9.7%), oppositional defiant disorder (ODD; 8.9%), social anxiety (8.8%), obsessive-compulsive disorder (OCD; 1.9%), dysthymia (1.4%), posttraumatic stress disorder (PTSD; 1.4%), anorexia nervosa (0.9%), panic (0.5%), and conduct disorder (0.5%). There were no significant differences in comorbid diagnoses between treatment groups.

There were no significant differences between therapy arms in regard to the mean number of individual sessions (CBT 9.1, SNDT 8.6), mean individual treatment minutes (CBT 374.1, SNDT 331.4), mean parent treatment minutes (CBT 93, SNDT 72), and mean percentage of phone sessions (CBT 62.8, SNDT 70.4). Although not significantly different, at least 6 sessions were completed by 91% of the CBT group compared to 74% of the SNDT group.

Note: Demographic information is given by portion of whole, where gender is broken down by male and female, site by Pittsburgh vs. Boston, and race by white vs. black. CBT = cognitive behavioral therapy; CDI = Children’s Depression Inventory; CDRS-R = Children’s Depression Rating Scale—Revised; CGAS = Children’s Global Assessment Scale; PCDAI = Pediatric Crohn’s Disease Activity Index; PUCAI = Pediatric Ulcerative Colitis Activity Index; SES = socioeconomic status; SNDT = supportive nondirective therapy.

*Indicates statistical significance.

**IMPACT-III is a health-related quality-of-life assessment.

For CBT, the percentage of participants where core CBT skills covered ranged from 70% to 100%. For SNDT, the percentage of participants with CBT skill contamination was <6%. SNDT was rated highly (>50% of participants) for the following content/processes: discusses physical/health symptoms (74%); encourages to talk (74%); clarifies or restates communication (89%); is sensitive to feeling (99%); and asks for information (99%). Together, these results demonstrate adequate fidelity.

Intervention Effects on Depression, Health-related Adjustment, and Disease Activity

As the primary aim, CDRS-R improved over time in both treatment groups, with no statistical differences (raw means at month 3 were 29.11 for CBT versus 32.18 for SNDT) (Table 3). Because there were baseline differences with CDRS-R, we fitted an additional model allowing the baseline scores for treatment group to be different, and results were similar to the original analysis. There were large pre–post effect sizes for each treatment over time (d = 1.31 for CBT and d = 1.30 for SNDT).

For secondary analyses, at 3 months, 50.3% of participants (n = 178) were found to have CDRS-R scores ≤28. Participants who received CBT had a nonsignificant higher percentage of treatment response (53.5% versus 47.1%) and showed a 29% increased odds of response (odds ratio [OR] = 1.29, 95% CI = 0.71–2.36) compared to individuals who received SNDT. At 3 months,
65.5% of the total sample (N = 217) no longer met DSM-IV-TR criteria for depression. There was no significant difference in remission rates between therapies (CBT 67.7% versus SNDT 63.2%). The CBT group had a nonsignificant 22% increased odds (OR = 1.22, 95% CI = 0.66–2.28) of remitting compared to the SNDT group. In comparing participants whose depression remitted versus those whose depression did not remit, there were greater percentages of youth with social anxiety (p = .03) and dysthymia (p = .04) in those whose depression did not remit. Those with non-remitting depression also had more IBD activity at 3 months (p = .02).

Although both therapies demonstrated improvement in HRQoL and psychosocial functioning at 3 months, there were no significant differences between treatments (Table 3). Mean IMPACT-III scores (CBT 142.52 versus SNDT 133.85) were consistent with a moderately good quality of life. Mean CGAS scores (CBT 65.82 versus SNDT 64.30) were consistent with minimal impairment. Controlling for surgery and race had no significant impact.

IBD activity improved over time in both treatment groups (raw means [standard deviations] at baseline to month 3: PCDAI: CBT 21.0 [16.2] to 9.49 [2.48] and SNDT 25.8 [3.8] to 15.30 [12.11]; PUCAI: CBT 23.3 [24.9] to 11.39 [12.7] and SNDT 22.4 [16.9] to 11.47 [16.56]). Pooled PCDAI and PUCAI z scores showed a statistically significant difference in reducing disease activity, favoring CBT over time (Table 3, p = .04).

## DISCUSSION

This study represents the largest randomized controlled trial of 2 psychotherapy interventions for youth with comorbid IBD and depression. Both the CBT and SNDT were associated with reduced depression severity, improved health-related adjustment, and lessened IBD activity over time. In comparing PASCET-PI to SNDT, there were no significant differences between treatments in the primary outcome, depressive severity, and in the secondary outcomes, only the difference in reduction of IBD activity reached significance, favoring CBT.

Although it is possible that the improvements in the primary and secondary outcomes measures for each intervention might have been related to passage of time, it seems unlikely, given our previous randomized trial showing that CBT was better than treatment as usual in improving depression and functioning in subsyndromal adolescent depression. SNDT is a recognized active therapy for childhood depression as evidenced by improvement in depression and suicidality, and, in some circumstances (e.g., history of abuse), it has been found to be more efficacious than CBT.

We cannot rule out factors common to both therapies (e.g., empathic attention, social support, probing the illness narrative, and family component) as contributing to the improvements. Having the same therapists providing both therapies is both a methodological strength, in that there is control for a large number of therapist characteristics that could affect

<sup>b</sup>Indicates statistical significance CBT > SNDT.
outcomes, as well as a potential limitation, as using the same therapists for both interventions may reduce treatment differences. Fidelity rating showed good fidelity for CBT and little therapist drift toward CBT in the SNDT group. In the context of the long-standing controversy in psychotherapy research between those who believe that psychotherapy works through the influence of specific theory-linked skills\(^44\) and those who believe that therapy works through “common factors,”\(^45,46\) our findings suggest that the specific modality-linked skills may be less important for the improvement of overall depression.

In secondary analyses of depression, almost 66% of our sample achieved remission of their depression, with 78.4% having <3 residual depressive symptoms. These rates are higher than those seen in treatment of physically healthy youth with depression.\(^47\) Certainly, the higher remission rates in our study may be explained by many factors, including less severe depression, lower comorbidity, higher treatment adherence, and/or strong support from the gastroenterologists. Yet, in another comparison of CBT and supportive therapy in adolescent depression without physical illness, a 64% CBT remission rate versus only 39% for supportive therapy was found.\(^21\) Both PASCET-PI and SNDT had large pre–post effect sizes (d = 1.3), which are comparable to those calculated to this adolescent depression psychotherapy trial (d = 1.68 for CBT and 1.58 for supportive therapy).\(^21\) Together, these findings provide further support for the premise that both CBT and SNDT were beneficial.

Although both therapies had a favorable impact on disease activity, CBT had a more favorable impact than SNDT. Baseline adherence with IBD medications was high and thus unlikely to be a reason for improved IBD activity. Given a mean 2-year IBD duration combined with participants’ improved HRQoL and psychosocial functioning, the findings are commensurate with reduced depression after psychotherapy, suggesting that these treatments provided additional benefit over and above standard medical treatment. Psychosocial interventions may enhance the brain’s capacity to regulate immune response in patients with IBD.\(^48\) In this context, it is possible that, for illness-specific processes (e.g., systemic inflammation), a more specific psychotherapy skill modality (e.g., CBT) may prove to be more helpful. However, these preliminary findings should be interpreted cautiously, given the pooling of IBD subtypes to measure disease activity, the significant number of participants with mild illness ratings, and the possibility of a type I error without correcting for multiple comparisons.

It is possible that factors that were significantly different between the 2 groups (more minority participants, depression severity differences, and higher surgery rates were found among those treated with SNDT) may have influenced outcomes. Depression is frequently considered a heterogeneous condition with different subtypes and unique etiologies. The presence of different depressive symptom clusters may have further confounded the unique therapeutic effects of CBT versus SNDT.\(^11\) Finally, although CD and UC are subtypes of IBD, they have different pathogeneses and thus may be affected differently by psychotherapy,\(^7\) as other treatments such as systemic steroids have differential behavioral and cognitive effects in youth with CD versus UC.\(^49\) It will be important to explore the effects of psychotherapy in more homogeneous subsets of youth to better understand the mechanisms that underlie effective psychotherapy in these illnesses.

Unfortunately, one-third of the youth continued to have persistent depressive illness despite psychotherapy, suggesting a need for alternative treatments. This subset had higher rates of social anxiety (n = 8 versus n = 5) and dysthymia (n = 3 versus n = 0) and more IBD activity at 3 months compared to those who achieved remission of depression, suggesting these 3 conditions may be treatment moderators. As there are no randomized controlled trials of antidepressants in youth experiencing both IBD and depression,\(^50,51\) future studies are needed to investigate the potential benefits and risks of psychotropic medication when added to the medical treatment.

Major strengths of this study are being the largest randomized treatment trial and showing that 2 different types of psychotherapy may be useful in treating depression in youth with high-morbidity chronic physical disease such as IBD. Potential study limitations include possible selection bias by recruiting participants with only mild to moderate depression. However, only 7 participants were excluded because of more severe depression (with 6 of these individuals being on antidepressants), and thus any bias would appear to be slight. Although our results would be strengthened by analyses of possible moderators (e.g., age, IBD type), the study was not designed to accomplish this goal. The relatively short follow-up period represents another
potential limitation. Although more than 50% of the sessions were conducted by telephone in both groups, possibly improving treatment adherence, we did not design the study to compare their efficacy.

Depression in individuals with chronic physical illness is a significant public health problem that is common, disrupts normal development, and causes substantial functional impairment. This study provides evidence that active psychotherapy may be a useful adjunct to medical treatment in youth with IBD during a developmental period in which patients are early in the course of a lifelong illness and vulnerable to increased psychopathology. It underscores the importance of integrating behavioral health strategies directly into pediatric medical homes. Our findings in IBD may be applicable to youth struggling with depression in other chronic illnesses and thus may offer significant promise for a better quality of life for physically ill youth.
